Abstract

This design research builds on the idea to combine the strengths of traditional survey research with a more practice-oriented benchmarking approach. We present selfsurvey.org, an online survey platform that allows providing instant and respondent-specific feedback based on a scientifically grounded research model and a structural equation model-based prediction technique. Based on the partial least squares analysis results of a training dataset, selfsurvey employs a scoring algorithm to derive respondent-specific predicted scores, compares these with the observed scores, and provides visualized and text-based outputs. Our evaluation of selfsurvey in the context of a maturity benchmarking study provides an indication for the perceived usefulness of this artifact and its underlying scoring algorithm. We argue that this prediction-based approach, which goes far beyond the functionality of common univariate benchmarking tools, can be used for a wide range of survey studies and help increase the perceived relevance of academic survey studies to practice.

Keywords: Survey research, Structural equation models, Partial least squares, Multivariate prediction, Benchmarking, Design research

1 Introduction

The debate about rigor and relevance continues to concern the Information Systems (IS) field and its neighboring management disciplines alike (e.g., Benbasat and Zmud, 1999, Boyer, 1996, Straub and Ang, 2011, Van De Ven and Johnson, 2006). Especially survey research is frequently charged with the claim to produce results that are somewhat detached from practice and response rates in academic surveys have been declining for years (Anseel et al., 2010). Survey research is different from case research in the sense that it normally aims to test a-priori hypothesized relationships between a set of variables (the research model) across a broad range of different settings (Benbasat et al., 1987). Practitioners, however, usually desire rich prescriptions to be applied in their specific organizational settings (Benbasat and Zmud, 1999). Given that results from survey studies are typically published on the aggregate level only and rarely find their way back to the respondents, survey research can easily be regarded as a ‘one-way’ approach that feeds observations from the real-world environment to the knowledge base, without sufficiently closing a cycle of ‘rigor and relevance’ (Hevner et al., 2004).

At the same time, some researchers have also long highlighted the importance of more practitioner-oriented benchmarking studies that enable firms to compare themselves with others. Even if these studies are often “actually a by-product rather than the primary outcome of […] academic research”,
they “tend to be of great interest to practice” since “there is understandably a desire to evaluate yourself against your peers” (Benbasat and Zmud, 1999, p. 11). Common benchmarking approaches, however, typically base their feedback merely on univariate score aggregation and thus lack the scientific foundation of the variables and their theoretical relationships in a research model (e.g., IBM, 2014, iGrafx, 2014, NSAFR, 2014). Therefore, the question arises: how can we provide participants with timely and relevant feedback that still leverages the a-priori knowledge encoded in a multivariate research model hypothesized by the researcher?

Following a design research approach, we developed selfsurvey.org, an online survey platform that upon completion of a questionnaire can provide instant feedback to participants based on a specified research model and a multivariate prediction technique. Using training data and a conceptual model specified by the researcher, selfsurvey derives respondent-specific predicted scores and compares these with observed scores as provided by the respondents. This comparison allows respondents to assess the extent to which their answers differ from what a research model suggests. The use case diagram in Figure 1 illustrates the two main user groups addressed by our artifact and exemplifies how selfsurvey intends to facilitate their knowledge exchange in an IS research cycle.

**Figure 1. Use case diagram (inspired by Hevner et al. (2004))**

The development of the selfsurvey platform considered the following four design requirements: (1) relevance to participants by providing them with timely and meaningful feedback, (2) rigor by applying state-of-the-art prediction methods, (3) usability by implementing an easy-to-use web application, and (4) generalizability by being applicable in different research domains. As a proof-of-concept, we evaluated selfsurvey in a maturity study in the context of IT service management, where predicted variable scores derived from training data were interpreted as ‘benchmarks’ of maturity and observed scores as ‘as-is’ levels. Survey respondents had the possibility to provide short qualitative statements (positive/negative), which provide descriptive evidence for the usefulness of selfsurvey and its underlying prediction and feedback mechanisms.

In the remainder, we first explain the methodological foundations that are crucial to understand the scoring algorithm implemented to our artifact. We then explain the design approach, expose details about the selfsurvey implementation, and show the results of its evaluation. Finally, we offer a brief review of related projects and a conclusion.

## 2 Foundations: Structural Equation Models in Survey Research

Selfsurvey builds on the principles of structural equation modeling (SEM) to provide a state-of-the-art multivariate prediction mechanism. SEM has become a quasi-standard in IS and other disciplines as it allows researchers to analyze series of interrelated dependence relationships between (unobserved) conceptual variables, measured by sets of indicator variables, while simultaneously accounting for measurement error (Ringle et al., 2012).

Consider Figure 2 for a sample path model, which illustrates the relationships between three conceptu-
al variables in the inner model ($\eta_1$, $\eta_2$, and $\eta_3$) and between each conceptual variable and its corresponding indicators in reflective outer models (e.g., $x_3$ and $x_4$ as indicator variables of $\eta_2$) or formative outer models (e.g., $x_1$ and $x_2$ as indicator variables of $\eta_1$). In a reflective outer model, indicators are seen as functions of the conceptual variables and changes in the conceptual variable are reflected in changes in the indicators. Reflective indicators are linked to their conceptual variables through loadings ($\lambda$), which represent zero-order correlations between the two elements (indicators of $\eta_2$ and $\eta_3$ in Figure 2). In contrast, in formative outer models, indicators are assumed to ‘cause’ a conceptual variable; changes in the indicators entail changes in the value of the concept (MacKenzie et al., 2011). Therefore, the relationships go from the indicators to the conceptual variable (indicators of $\eta_1$ in Figure 2). These relationships are represented by weights ($\pi$), which indicate the unique importance of each indicator by partializing the variance of the conceptual variable that is predicted by the other indicators (Cenfetelli and Bassellier, 2009).

**Figure 2. Structural equation model example**

The inner model from Figure 2 is given in Equations 1 and 2, where $\zeta_2$ and $\zeta_3$ are the error terms of the dependent conceptual variables $\eta_2$ and $\eta_3$.

$$\eta_2 = \beta_2 \eta_1 + \zeta_2, \text{ and}$$  
$$\eta_3 = \beta_1 \eta_1 + \beta_2 \eta_2 + \zeta_3$$  

Equation 3 describes the formative outer model of $\eta_1$, where $\zeta_1$ is the error term of the conceptual variable. Finally, Equation 4 describes the outer model of a reflectively measured conceptual variable $j$ (here $j=2$; and 3), where $\epsilon_i$ is the error term associated with the indicator variable $i$ (here $i=3$, 4; and 5, 6, 7 respectively).

$$\eta_1 = \pi_1 x_1 + \pi_2 x_2 + \zeta_1$$  
$$x_i = \lambda_i \eta_j + \epsilon_i$$

To estimate the parameters of a path model, researchers can revert to composite-based methods like partial least squares (PLS) or factor-based methods such as covariance-based SEM (Jöreskog and Wold, 1982). While factor-based SEM has long been the predominant approach to analyze path models, PLS use has recently gained momentum in a variety of fields, including IS (Ringle et al., 2012), marketing (Hair et al., 2012b), management (Hair et al., 2012a) and related disciplines (e.g., do Valle and Assaker, 2015, Richter et al., 2015). Different from factor-based SEM, PLS has been designed as a prediction-oriented approach to SEM that relaxes the demands on data and specification of relationships (Dijkstra, 2010, Jöreskog and Wold, 1982, Rigdon, 2012). One main advantage of PLS over factor-based methods is, that it yields determinate predictions, while factor-based methods’ prediction is constrained by factor indeterminacy (Becker et al., 2013). Factor indeterminacy entails that the correlation between a common factor and any variable outside the factor model is itself indeterminate,
which makes factor-based SEM grossly unsuitable for prediction (Becker et al., 2013, Rigdon, 2012). In contrast, PLS produces determinate scores for each conceptual variable based on linear combinations of the indicators and their weights. More precisely, PLS constructs proxies of the conceptual variables in the form of linear composites by means of “a sequence of alternating least squares algorithms, each time solving a local, linear problem, with the aim to extract the predictive information in the sample” (Dijkstra, 2010). Evermann and Tate’s (2014) recent simulation study underlines PLS’s superior predictive ability compared to factor-based SEM and simple regression methods.

An important feature of PLS, reproduced by selfsurvey is the computation of the scores of conceptual variables in the PLS algorithm (for a detailed description of the PLS algorithm see Tenenhaus et al., 2005). Initially, in the ‘inner approximation,’ PLS creates inner proxies of each conceptual variable, which form the foundation for the estimation of the model parameters (i.e., loadings, weights, and path coefficients). The inner proxy of a conceptual variable is a type of weighted sum of the scores of other conceptual variables in the model depending on the inner weighting scheme. These inner proxies are then updated in the ‘outer approximation’ by means of linear combinations of indicator scores and proxies of the indicator weights. The indicator weights are an important element in that they are used to form the inner proxies, regardless of whether the outer model is reflective or formative. The inner and outer approximation run iteratively until the indicator weight estimates converge (e.g., Tenenhaus et al., 2005). Based on this concept, selfsurvey computes respondent-specific scores of the dependent conceptual variables from its indicator variables (observed scores) and compares these to the scores computed from its antecedent conceptual variables, based on a given model and parameter estimates from a training dataset (see Section Scoring Algorithm).

3 Design Approach and Artifact Development

The development of selfsurvey follows a design science paradigm. Design science provides a methodological frame for constructive research in IS that “focuses on creating and evaluating innovative IT artifacts that enable organizations to address important information-related tasks” (Hevner et al., 2004, p. 98). Hevner et al. provide seven guidelines for effective design research that we address at different stages of our research. These guidelines relate to (1) design of the artifact, (2) problem relevance, (3) evaluation, (4) research contribution, (5) research rigor, (6) design as a search process, as well as (7) communication of the research. We formulated four design requirements for the development of our artifact that relate to these guidelines:

- **Relevance:** The artifact should provide timely and useful feedback to survey participants after completion of a questionnaire, including dynamically generated graphical textual outputs.
- **Rigor:** Feedback provided by the artifact should—beyond descriptive statistics—be based on state-of-the-art multivariate inference methods (e.g., SEM-based prediction), and be able to
  - handle the use of continuous and discrete variables, and
  - operationalize academic theory for a practitioner audience.
- **Usability:** The artifact should have the look and feel of a modern web application, including easy navigation and multi-language support.
- **Generalizability:** The principles applied in this artifact should be applicable across a wide range of contexts and the artifact should be easy to reuse for different survey studies.

Regarding guideline 6, the **design process** was iterative, comprising several periods with different developers working on the artifact at different times, and entailed principles of user-centered design. In 2011, we started building this artifact without drawing on existing survey tools to make this proof-of-concept independent from other third-party software. A first version of selfsurvey, which was finished early 2012, focused on the platform front-end including the creation of different survey question types as HTML elements. A second version then focused on the re-usability by rendering questionnaires from independent XML file inputs and, amongst others, also improved the prediction functionality. This version was live tested early 2013 in a think-aloud meeting with a CIO, who filled out an
example questionnaire (different from the one that the evaluation in this paper is based on) and reviewed the feedback page. Based on this preliminary evaluation, a third version was built that shifted some of the application logic to the client side (using JavaScript) and introduced asynchronous web techniques (AJAX) for a more seamless user experience when navigating in a survey. The fourth and final version, which this paper is based on, made significant improvements foremost in the visualization of feedback results on the conceptual variable as well as on the indicator levels. For this purpose, interviews with three IT professionals were conducted early 2014 to improve the visualization capabilities and finalize the work.

Addressing guideline 3, the main evaluation of the artifact was performed in the course of a field study on a specific maturity phenomenon. First, this evaluation should demonstrate if and how the artifact can be applied in a concrete survey project. Second, under the assumption that the perceived relevance of this specific selfsurvey project would be reflected in the respondents’ overall user experience with this survey tool, we added an additional (but optional) questionnaire page, where survey respondents were encouraged to provide short statements. The details and results of this proof-of-concept and qualitative user evaluation are presented in Section Evaluation.

4 Artifact: Selfsurvey Platform and Algorithm

In this section, we first describe selfsurvey’s technical architecture in which the SEM scoring algorithm is embedded, before explaining the algorithm as such more formally.

4.1 Technical Architecture

Selfsurvey is built on standard web technologies such as PHP for the server-sided logic, JavaScript for the client-sided logic, and MySQL for the database as well as an XML file for the configuration of a survey project. The overall architecture including the main PHP modules is depicted in Figure 3. In the following, we will walk through this diagram, starting with the initial request of a survey respondent.

A survey respondent opens the web browser and requests the selfsurvey website from the webserver. The server-side logic follows a ‘model-view-controller’ architectural design pattern (e.g., Fowler, 2003). For the initial request, the Index.php acts as the ‘controller’ that processes the user request and returns the entire HTML page output including the first questionnaire page, as well as all remaining pages as hidden elements. All of the following user interactions (e.g., change a page) are handled directly on the client side whereas relevant data is exchanged asynchronously in the background as JSON arrays between the client and the server (AjaxQueries.php), which on client-side is handled by the functions of Main.js. The Ajax-queries module then acts as the ‘controller’ for all subsequent interactions (e.g., reading and writing respondent data, and finally triggering the scoring). Both In-

![Figure 3. Web application architecture (simplified scheme)](image-url)
dex.php and AjaxQueries.php make use of the functions of Viewer.php for creating HTML output, including the different questions that populate the questionnaire page (needed initially by Index.php) as well as the feedback page that is created dynamically after filling out the survey (transmitted by AjaxQueries.php). Thus, the appearance of the website is determined by Viewer.php (plus additional CSS style definitions).

The web application behavior (the ’model’) for a specific survey project is configured in a Survey.xml file. It contains three major sections: the configuration of the path model, the questionnaire, and the feedback page. The path model section defines the variables, their indicators and relationships including weights and loadings as specified by the researcher. It can also handle multiple parallel path models in case a research model contains a categorical moderator and has been estimated for multiple training sets (e.g., different path models for male and female participants). The chosen path model then depends on the respondent’s input. The questionnaire section defines the actual flow of questions, texts and page breaks, mapping each of the input questions to relevant indicators of the path model. Different question types are currently available, such as one-way matrix (e.g., for Likert items), two-way matrix (for bipolar items), vertical radio buttons, check boxes as well as numerical inputs and text inputs. All texts can be specified in different languages. The feedback section of the Survey.xml file defines how individual scoring results are presented to the respondent after filling out a survey. This feedback can include different types of bar charts and spider diagrams for dependent variable scores and indicator level values (both realized using third party APIs). Additional text elements can be specified here that help to interpret the visual results.

To avail a specific survey configuration at run-time, the survey’s XML is first validated syntactically through an XML schema definition (XSD) once a new project is initialized, then parsed into a global configuration object and finally serialized into a binary file that can be quickly reloaded every time a new survey respondent starts a session. This global object, which is provided by XmlModel.php, also implements the routines of the scoring algorithm, which start from the dependent variable and recursively calculate the scores of the path model variables (see next Section). The persistent data for this web application is stored in a relational database that comprises the user input data as well as the training data that the path models are based on. Standardized indicator values and variable for both, user data and training data are stored in separate tables. All read/write operations to the data model (i.e., all SQL queries) are encapsulated by DataModel.php; with one minor exception: The web application also catches potential JavaScript runtime errors at client-side through an error handler that logs these directly in a separate database table.

### 4.2 Scoring Algorithm

The working principle of the scoring algorithm, which is at the core of selfsurvey, builds on the PLS algorithm and follows a five-step procedure: (1) Calculation of observed conceptual variable scores, (2) calculation of predicted conceptual variable scores, (3) calculation of predicted indicator values, (4) transformation to original scales, and (5) comparisons. The variables for our path model example and the five-step algorithm are depicted in Figure 4.1

Prerequisite (Step 0) for this procedure is that the standard PLS algorithm has previously been run on a training dataset to obtain weight, loading, and path coefficient estimates.2 This training dataset may stem from a pre-test or from a prior study and needs to fulfill standard sample size requirements (e.g.,

---

1 Note that Figure 4 includes both, indicator loadings and weights as both elements are used in the course of the ’outer approximation’ stage of the PLS algorithm. The interpretation of model estimates, however, primarily focuses on indicator loadings for reflective measures and indicator weights for formative measures (Hair et al. 2014).

2 Several software tools are available to estimate the path model (Step 0); for an early overview, see Temme et al. (2010).
Hair et al., 2014). Furthermore, model estimates must exhibit sufficient levels of reliability and validity (e.g., Hair et al., 2012b). Using these estimates, Steps 1–4 of the scoring algorithm calculate individual case values for each respondent.

In Step 1, analogous to the ‘outer approximation’ in the PLS algorithm (Tenenhaus et al., 2005), observed conceptual variable scores are calculated as linear combinations of the associated (standardized) observed indicators ($x'_i$) and their weights as obtained from step 0. As the computation of conceptual variable scores in PLS builds on indicator weights, regardless of the outer model specification (Tenenhaus et al. 2005), Step 1 universally applies to reflective and formative outer models. For this purpose, all indicator variable values are initially transformed to $z$-values using the means $\bar{x}_i$ and standard deviations $s_i$ from the training set:

$$z'_i = \frac{x'_i - \bar{x}_i}{s_i} \quad (5)$$

The observed conceptual variable scores are then given by:

$$\eta'_j = \sum_i \pi_i z'_i \quad \forall \text{ indicators } i \text{ of conceptual variable } j \quad (6)$$

Step 2 involves the calculation of the predicted scores $\hat{\eta}$ for each conceptual variable. The algorithm starts with the independent conceptual variables whose predicted scores are identical to the observed scores as obtained in Step 1. Thus, for the model in Figure 4, the following holds:

$$\hat{\eta}_1 = \eta'_1 \quad (7)$$

For the dependent conceptual variables, the algorithm recursively iterates through the antecedent variables. More precisely, the predicted scores are given as a linear combination of the (predicted) ante-

---

3 In case such training data is not available at the time of executing an initial survey, selfsurvey also provides the possibility to first conduct a survey and then provide the scoring results at a later point in time, for example, after updating the research model and sending an email notification (see Figure 1).

4 The prime symbol ($x'$) indicates that the values are observed for a specific respondent.
Predicted item values $\hat{x}_i$ range on the original scale levels (e.g., seven-point Likert scales) as continuous values (non-integers) that can be interpreted by the survey participant according to the original scale descriptors (e.g., strongly disagree, disagree, somewhat disagree, neutral, etc.).

In a similar manner, we back-transform conceptual variable scores to semantically interpretable scales. We can calculate the sample variances $\text{Var}(Y)$ and expected values $E(Y)$ of the conceptual variables from the weighted linear combinations of the original indicator values and transform the predicted scores $\hat{\eta}$ into predicted scaled scores $\hat{Y}$, and the observed scores $\eta'$ into observed scaled scores $Y'$ using the following equations (e.g., Mulaik, 2010):

$$\hat{Y}_j = \sqrt{\text{Var}(Y_j)} \hat{\eta}_j + E(Y_j),$$

$$Y'_j = \sqrt{\text{Var}(Y'_j)} \eta'_j + E(Y'_j),$$

where

$$\text{Var}(Y_j) = \text{Var}(\sum_{i=1}^j \pi_i x_i) = \sum_{i=1}^j \pi_i^2 s_i^2 + 2 \sum_{i=1}^{j-1} \sum_{k=i+1}^j \pi_i \pi_k \cdot \text{Cov}(z_i, z_k)$$

$$E(Y_j) = E(\sum_{i=1}^j \pi_i x_i) = \sum_{i=1}^j \pi_i \bar{x}_i \forall \text{ items } i, k \leq \eta_j \text{ of a conceptual variable } j.$$

Finally, Step 5 involves comparing the (scaled) observed and predicted variable scores on both, the indicator ($\delta_i$) and conceptual variable ($\Delta_j$) levels. The differences $\delta_i$ and $\Delta_j$ can be interpreted as deviations of a user’s original responses from how individuals with similar independent variable characteristics have rated themselves on this specific variable.

$$\delta_i = x'_i - \hat{x}_i$$

$$\Delta_j = Y'_j - \hat{Y}_j$$

The differences $\delta_i$ and $\Delta_j$ are continuous but may be rounded for simplicity. In addition, selfsurvey allows specifying thresholds (e.g., -1.5; -0.5; 0; 0.5; 1.5) to define whether observed values are considered much less, less, equal, greater, or much greater than the predicted values to provide feedback to the respondents. Specifically, for each level of deviation, selfsurvey can provide text elements—which the researcher predefines—to help the respondent interpret the deviation and make sense out of the abstract numeric differences.

5 Evaluation: Using Selfsurvey to Study Maturity Phenomena

We evaluated selfsurvey in the context of a larger study on maturity of IT service management (ITSM) processes. For reasons of brevity, in this section we only briefly explain the study background and the survey’s key variables. Instead, we focus on how the training dataset was collected and how the selfsurvey scoring algorithm facilitated the provision of feedback to the survey participants. Finally, we present the results of the participants’ qualitative evaluation of selfsurvey.

5.1 Study Background and Survey Design

The concept of maturity has high relevance to IS practice and is also becoming an increasingly important subject of IS research (Becker et al., 2010). Maturity can generally be understood as “as a measure to evaluate the capabilities of an organization in regards to a certain discipline” (Rosemann and de Bruin, 2005). Maturity models have been proposed within different areas of application, for example, for software engineering (Paulk et al., 1993), business process management (Rosemann and de Bruin, 2005), e-government (Andersen and Henriksen, 2006), and ITSM (CMMI-SVC, 2010). Especially research on ITSM is still in its early development stage with mostly descriptive works on common ITSM frameworks and few case studies on benefits and challenges of ITSM implementations (Marrone and Kolbe, 2011).

The study used to evaluate and illustrate the capabilities of selfsurvey addresses this gap in research by investigating the impact of antecedents of ITSM process maturity. ITSM process maturity is conceptualized as the maturity of “a set of specialized organizational capabilities for providing value to customers [...] in the form of functions and processes for managing services over a lifecycle” (OGC, 2011). Specifically, the study builds on the IT Infrastructure Library (ITIL), which is the most widely applied framework for ITSM (Marrone and Kolbe, 2011), and measures ITSM process maturity in each of ITIL’s four main lifecycle areas (service strategy, service design, service transition, and service operation) as separate variables, based on the maturity of their 26 constituting processes (6, 8, 7, and 5 processes, respectively). The maturity of each of these processes (e.g., incident management, problem management, and change management) is measured on six-point scales with the descriptors ‘none,’ ‘initial,’ ‘repeatable,’ ‘defined,’ ‘managed,’ and ‘optimized’ used in the well-known Capability Maturity Model (CMM, Paulk et al., 1993). The survey explains each scale level to the respondent by detailed descriptors which have been derived from CMM-based frameworks that fit this study’s ITSM context (e.g., CMMI-SVC, 2010).

Independent variables that potentially predict the maturity of the ITSM processes in each of the ITIL stages have been derived from prior literature and were operationalized using established measures. These predictors relate to both properties of the organization, such as organization size (measured by common logarithm of the number of employees), industry type (manufacturing vs. service) and IT strategy (innovative vs. conservative), as well as properties of the IT services provided, such as their business criticality (high vs. low) and expected service levels (high vs. low). Each of these variables is hypothesized to have relationships to the dependent variables. For example, larger organizations are expected to exhibit a greater maturity in their ITSM processes. In addition, respondents have to indicate the relevant type of IT service provider (internal IT unit, shared service IT unit, or external service provider). The service provider type acts as a categorical moderator in the model as antecedent-to-dependent variable relationships may differ for different types of IT service providers.

For more details on the study including the measures of the dependent variable we refer to Wulf et al. (2015).
### 5.2 Training Dataset and SEM Scoring

The training dataset, whose model estimates facilitate calibrating the feedback on predicted levels of ITSM process maturity, was collected mid 2013 from IT professionals (IT managers, IT service management experts, consultants) using a standard survey platform. This initial study (the pretest of the actual survey) yielded $n_{1} = 24$ usable responses, which were used to estimate a *baseline model* with a reduced number of independent variables and no use of the categorical moderator ‘type of service provider.’ Despite the comparably low sample size in relation to the model complexity, all model evaluation criteria were met (e.g., Hair et al., 2012b) and path coefficients were plausible in magnitude and sign. Therefore, the results of the baseline model analysis offer a sound basis for providing the users with preliminary feedback.

In the follow-up study during late 2013, we collaborated with a leading professional association and invited ITSM practitioners from Germany, Denmark, and Switzerland to participate in our research. The follow-up study relied on the third version of selfsurvey (see section Design Approach) and provided users with preliminary feedback based on the *baseline model* estimates. In light of the sample size restrictions in the initial study, we pointed out the preliminary nature of the results, announcing that further results based on a broader empirical basis will be provided. This second stage yielded $n_{2} = 130$ usable responses, which were subsequently used to estimate an *updated model* with two additional independent variables and separate models for internal IT units ($n_{2a} = 60$), shared service IT units ($n_{2b} = 41$), and external service providers ($n_{2c} = 29$). Table 1 illustrates the key differences between the baseline model and updated model version of the ITSM selfsurvey project.

In line with the scoring algorithm, ‘as-is’ (i.e., observed) levels result directly from the user assessment of current ITSM process maturity levels. Benchmark (i.e., predicted) levels result from the user inputs on the independent variables (such as organization size, industry, IT strategy, and expected IT service levels) and can be interpreted as average levels of process maturity of organizations with similar characteristics regarding the aforementioned predictors. The analysis of deviations between observed and predicted scores and indicator values was labelled a ‘gap analysis’ and included explanations of the method for the practitioner audience. Furthermore, the descriptions stressed that the benchmark scores do not necessarily represent ‘optimal’ levels.

Figure 5 displays two visualizations generated by selfsurvey: A bar chart to display scaled conceptual variable scores (here: ITSM process maturity in the service operation area, binned into 0.5 point intervals), and a spider diagram to display scaled indicator values (here: the maturity of each of the processes in the ITSM service operation area in continuous values). For the binned conceptual variable scores, selfsurvey additionally displayed the relative distributions of the training data scores (1) of responses in the same category (here: the same service provider type, termed ‘peer group’), and (2) of all responses (grey bars in Figure 5).

**5.2 Training Dataset and SEM Scoring**

The training dataset, whose model estimates facilitate calibrating the feedback on predicted levels of ITSM process maturity, was collected mid 2013 from IT professionals (IT managers, IT service management experts, consultants) using a standard survey platform. This initial study (the pretest of the actual survey) yielded $n_{1} = 24$ usable responses, which were used to estimate a *baseline model* with a reduced number of independent variables and no use of the categorical moderator ‘type of service provider.’ Despite the comparably low sample size in relation to the model complexity, all model evaluation criteria were met (e.g., Hair et al., 2012b) and path coefficients were plausible in magnitude and sign. Therefore, the results of the baseline model analysis offer a sound basis for providing the users with preliminary feedback.

In the follow-up study during late 2013, we collaborated with a leading professional association and invited ITSM practitioners from Germany, Denmark, and Switzerland to participate in our research. The follow-up study relied on the third version of selfsurvey (see section Design Approach) and provided users with preliminary feedback based on the *baseline model* estimates. In light of the sample size restrictions in the initial study, we pointed out the preliminary nature of the results, announcing that further results based on a broader empirical basis will be provided. This second stage yielded $n_{2} = 130$ usable responses, which were subsequently used to estimate an *updated model* with two additional independent variables and separate models for internal IT units ($n_{2a} = 60$), shared service IT units ($n_{2b} = 41$), and external service providers ($n_{2c} = 29$). Table 1 illustrates the key differences between the baseline model and updated model version of the ITSM selfsurvey project.

In line with the scoring algorithm, ‘as-is’ (i.e., observed) levels result directly from the user assessment of current ITSM process maturity levels. Benchmark (i.e., predicted) levels result from the user inputs on the independent variables (such as organization size, industry, IT strategy, and expected IT service levels) and can be interpreted as average levels of process maturity of organizations with similar characteristics regarding the aforementioned predictors. The analysis of deviations between observed and predicted scores and indicator values was labelled a ‘gap analysis’ and included explanations of the method for the practitioner audience. Furthermore, the descriptions stressed that the benchmark scores do not necessarily represent ‘optimal’ levels.

Figure 5 displays two visualizations generated by selfsurvey: A bar chart to display scaled conceptual variable scores (here: ITSM process maturity in the service operation area, binned into 0.5 point intervals), and a spider diagram to display scaled indicator values (here: the maturity of each of the processes in the ITSM service operation area in continuous values). For the binned conceptual variable scores, selfsurvey additionally displayed the relative distributions of the training data scores (1) of responses in the same category (here: the same service provider type, termed ‘peer group’), and (2) of all responses (grey bars in Figure 5).
In addition to this visual information, the feedback page of the ITSM survey was complemented with textual information to help interpret these charts. For example, a deviation of -1.0 or less of the scaled ‘as-is’ process maturity from the benchmark CMM levels (like in Figure 5, left side) was considered ‘much less’ and corresponding texts were prompted with specific measures from the maturity literature to improve the current state (e.g., through standardizing procedures, defining accountabilities, and initiating trainings, etc. (CMMI-SVC, 2010)). In contrast, a slight positive deviation of 0.5 to 1.0 CMM levels was considered a satisfactory outcome and no urgent need for action was indicated.

5.3 Qualitative User Evaluation

In addition to the questionnaire and gap analysis sections, the selfsurvey platform provided an additional evaluation page where participants of the ITMS study could indicate “one aspect that [they] liked” and “one aspect that [they think] could still be improved” about this survey tool. 25 out of the

Table 2. Evaluation comments by respondents (number of comments in brackets)
130 respondents from the first stage (baseline model version) of the ITSM study made use of this possibility and provided short statements. After we updated the prediction model and implemented the updated model improvements (described in Table 1), we received further evaluation statements from a different set of 22 respondents. We sorted these statements into nine emergent categories as statements about the survey content, survey clarity, and survey length; as well as those about ease of use, feedback functionality, visualizations, the methodology as such, and general comments about the tool. Table 3 displays the comments referring to the tool before and after the model update, given that these are of higher interest for the purpose of evaluation (and not those about the survey as such).

Although descriptive in nature, we believe one can see a tendency in these results, which asked equally for positive aspects and areas of improvement. First, the comments on the positive (upper) side provide a clear indication that the tool is perceived both as easy to use and as useful. The opportunity of receiving instant feedback is acknowledged positively by a majority of those who provided tool-related feedback. While many of the ‘improvement potentials’ (lower side) also have a positive tone, we also can see differences here between the baseline version and the updated version: While some users of the baseline model version are skeptical about the methodology and demand more sophisticated feedback mechanisms, these issues seem to have been successfully addressed in the updated model version. For the updated model version, remaining improvement potentials mainly revolve around advanced user wishes for specific functionality to print the assessment results—which, in turn, can again be viewed as an indication of perceived usefulness and perceived relevance of the feedback results to the study participants.

6 Related Projects

The idea of providing online self-assessment and benchmarking tools is not entirely new. Several websites are available by commercial providers that address, for example, business process management capabilities (iGrafx, 2014), online analytics maturity (CardinalPath, 2014), scientific innovation maturity (Accelrys, 2014), manufacturing excellence (EUBIZZ, 2014), retail business capabilities (NSAfR, 2014), or workforce and customer experience (IBM, 2014). The vast majority of these tools rely on simple score aggregations as univariate measures, sometimes complemented by certain industry or company size categories. In addition, some academics have used their data and models to provide online tools that let practitioners benefit from their research. Examples are the World Management Survey (WMS, 2014), the Organizational Culture Assessment Instrument (e.g., OCAI, 2014), and Hofstede et al.’s ‘Culture Compass’ (Hofstede, 2014).

Selfsurvey differs from these commercial as well as academic initiatives in at least two important ways. First, benchmarks provided by selfsurvey rely on predictions based on a validated path model that can be used in a far more context-specific way than the mere aggregation of empirical scores. Second, selfsurvey is designed as a multi-purpose platform that allows for great flexibility when specifying different survey projects by using separate XML configuration. This flexibility makes selfsurvey different from those academic tools that are solely designed for the specific purpose of a singular model. To the best of our knowledge, there is currently no other benchmarking platform that (1) implements SEM-based prediction, (2) allows researchers to flexibly specify different conceptual models, and (3) provides participants with instant feedback.

7 Conclusion

The potentials of combining state-of-the-art survey research methods with a more practitioner-oriented benchmarking approach motivated our development of selfsurvey.org, an online survey platform that can provide instant feedback to survey respondents based on scientifically grounded research models and a multivariate prediction technique. Based on the PLS analysis of a training dataset, selfsurvey derives respondent-specific predicted (benchmark) scores and compares these with observed scores of a respondent, thus allowing survey participants to assess the extent to which they deviate from what a
theoretically grounded path model suggests. We argued that the prediction and feedback mechanisms implemented in selfsurvey, which go far beyond commonly applied univariate comparisons, can leverage theoretical models specified by the researcher and generate meaningful information to practitioners, provided that the survey principally addresses a problem domain of their interest.

We demonstrated the use of selfsurvey in the context of a recent study in the domain of ITSM process maturity. The qualitative evaluation results indicate that respondents generally perceived selfsurvey as easy to use and that its feedback option was a useful functionality to them. It also suggests that the improvements made to the survey in the final update (i.e., increased training data, more sophisticated prediction model, detailed visualizations, more textual information) helped to address some of the prior shortcomings so that users of the updated model version see an even greater value in the survey’s feedback results (and want these to be printed or exported). Although our user evaluation did not consider whether the feedback results were ultimately of use in the respondents’ specific organizational settings, the feedback mechanism can still be deemed a necessary condition to increase the potential practical relevance of a survey. Compared to traditional ‘one-way’ studies, we therefore believe that the prediction and feedback mechanisms underlying selfsurvey can facilitate the knowledge exchange of researchers and survey respondents in an IS research cycle (Hevner et al., 2004) as well as other disciplines.

We argue that the final artifact satisfies the four initially set design requirements: (1) selfsurvey supports relevance to survey participants since it is able to provide comprehensive feedback including graphical visualizations (e.g., Figure 5) and case-specific textual information depending on the extent of observed deviation. (2) To provide the respondents with feedback, selfsurvey applies PLS, a rigorous and widely used method for prediction-oriented SEM. Selfsurvey can handle continuous variables as antecedents as well as categorical variables as moderators of antecedent relationships, and is therefore applicable to a broad range of theoretical models. (3) Selfsurvey matches the usability characteristics of modern web applications. (4) Finally, there are two levels of generalization that emanate from this research: On a conceptual level, other researchers may apply the SEM-based scoring algorithm in their own survey projects. On a practical level, we invite other researchers to use selfsurvey as a platform to make their own research accessible and experienceable for practitioners.

An important question is to which extent SEM-based prediction will be perceived relevant in other domains than for the maturity benchmarking that was the context for our evaluation. For example, in technology acceptance research it might be less relevant for a survey participant to learn about his/her predicted intention to use based on certain independent variables. As a simple guideline, we contend that SEM-based prediction may be most useful in research where the dependent variable represents a criterion from which a concrete ‘need for action’ emerges from the deviation between observed and predicted scores. However, since the question whether a model is relevant for practice is ultimately also a question of its theoretical underpinnings, we also concur with Benbasat and Zmud (1999, p. 6) when they stress that IS research should “develop and assess strong theoretical models such that prescriptive actions can confidently be suggested for practice.”

Limitations and future research relate to both the selfsurvey artifact and its evaluation. Selfsurvey, in its current version, supports continuous antecedent variables and categorical moderators. A future version might also address more complex interaction effects such as moderation between two continuous variables and quadratic effects. In light of recent research on the predictive capabilities of the PLS methodology (Becker et al., 2013), a future version of selfsurvey might also implement different modes for estimating conceptual variable scores (i.e., Mode A vs. Mode B model estimation, Henseler and Sarstedt, 2013), depending on the sample size, population $R^2$ and degrees of multicollinearity in the path model. Finally, by introducing selfsurvey to a broader base of researchers, we hope to facilitate the evaluation of selfsurvey in other research settings that allow deriving further recommendations on how to improve the platform and the underlying prediction mechanisms.
